Abstract

In this paper, we consider the role of “leads” of the first difference of integrated variables in the dynamic OLS estimation of cointegrating regression models. We demonstrate that the role of leads is related to the concept of Granger causality and that in some cases leads are unnecessary in the dynamic OLS estimation of cointegrating regression models. Based on a Monte Carlo simulation, we find that the dynamic OLS estimator without leads substantially outperforms that with leads and lags; we therefore recommend testing for Granger non-causality before estimating models.

JEL classification: C13; C22
Key Words: Cointegration; dynamic ordinary least squares estimator; Granger causality

1 Introduction

Since the seminal work of Engle and Granger (1987), cointegrating regressions have become one of the standard tools in analyzing integrated (I(1)) variables. Although the ordinary least squares (OLS) estimator is consistent in the presence of a serial correlation in the error term and/or a correlation between the regressors and cointegration errors, it is well known that the OLS estimator contains the so-called second-order bias. In the literature, there are three typical estimators that deal with this problem: the fully modified OLS estimator proposed by Phillips and Hansen (1990), Park’s (1992) canonical cointegrating regression estimator, and the dynamic OLS (DOLS) estimator of Phillips and Loretan (1991), Saikkonen (1991), and Stock and Watson (1993). These three estimators are known to be asymptotically equivalent and efficient. In this paper, we focus on the DOLS estimator among the three estimators and consider the role of “leads” of the first difference of the integrated variables in DOLS. We investigate the case where leads are unnecessary for the DOLS method, and by using the Monte Carlo simulation, we demonstrate that in such a case, we can expect the improvement of the DOLS estimator in terms of the mean squared error (MSE) by excluding leads from the regressors.

2 Relation between Leads and Granger Causality

We consider a typical cointegrating regression model as follows:

\[
\begin{align*}
    y_t &= \alpha + \beta' x_t + u_{1t} = \theta' z_t + u_{1t} \\
    \Delta x_t &= u_{2t}
\end{align*}
\]

where \(\theta = [\alpha, \beta]'\), \(z_t = [1, x_t']'\), \(x_t\) is an \(n\)-dimensional I(1) vector, and \(u_t = [u_{1t}, u_{2t}']'\) is a stationary process that satisfies the condition of the multivariate invariance principle. Under the regularity condition given in Saikkonen (1991), \(u_{1t}\) is expressed as

\[
    u_{1t} = \sum_{j=-\infty}^{\infty} \Pi'_j u_{2t-j} + v_t
\]

where \(\sum_{j=-\infty}^{\infty} ||\Pi_j|| < \infty\) and \(v_t\) is a stationary process such that \(E(u_{2s}v_t) = 0\) for all \(s\) and \(t\). See also Brillinger (1981). By inserting (2) into (1), the model can be expressed as

\[
    y_t = \alpha + \beta' x_t + \sum_{j=-K}^{K} \Pi'_j \Delta x_{t-j} + \dot{v}_t
\]

where \(\dot{v}_t = v_t + \sum_{|j| > K} \Pi'_j u_{2t-j}\) and \(K\) is known as the lead-lag truncation parameter. Saikkonen (1991) showed that the OLS estimator of \(\beta\) based on (3) does not suffer from the second-order bias and is efficient in a certain class of distributions.
Let us consider the case where
\[ \Pi_j = 0 \quad \text{for} \quad \forall j < 0. \quad (4) \]
In this case, the model becomes
\[ y_t = \alpha + \beta' x_t + \sum_{j=0}^{K} \Pi'_j \Delta x_{t-j} + \hat{v}_t \quad (5) \]
and then we do not have to include the leads of \( \Delta x_t \) as regressors. We therefore expect an improvement of the finite sample efficiency by estimating (5) because we do not have to include extra regressors. In this case, we note that condition (4) is related to the concept of Granger causality. According to Sims (1972) and Proposition 11.3 in Hamilton (1994), condition (4) holds if and only if \( u_{1t} \) does not Granger-cause \( u_{2t} \). In other words, it is possible to efficiently estimate the cointegrating regression model without any leads of the first difference of integrated variables if the past values of \( u_{1t} \) do not help to predict \( u_{2t} \). Therefore, we recommend that the null of Granger non-causality be tested before estimating the cointegrating regression model.

Tests for Granger non-causality can be conducted by approximating the process of \( u_t \) by a finite-order vector autoregressive model:
\[ u_t = \Psi_{11} u_{t-1} + \Psi_{21} u_{t-2} + \cdots + \Psi_{p1} u_{t-p} + \epsilon_t. \]
Let \( \hat{u}_t = [\hat{u}_{1t}, \hat{u}_{2t}]' \), where \( \hat{u}_{1t} = u_{1t} - (\hat{\theta} - \theta)' z_t \) is the regression residual from (1) with \( \hat{\theta} \) as the OLS estimator of \( \theta \). We then estimate
\[ \hat{u}_t = \hat{\Psi}_{11} \hat{u}_{t-1} + \hat{\Psi}_{21} \hat{u}_{t-2} + \cdots + \hat{\Psi}_{p1} \hat{u}_{t-p} + \hat{\epsilon}_t \quad (6) \]
and test the hypothesis that \( \hat{\Psi}_{121} = \hat{\Psi}_{221} = \cdots = \hat{\Psi}_{p21} = 0 \) where \( \hat{\Psi}_{j21} \) is the (2, 1) block of \( \hat{\Psi}_j \) and \( \hat{\epsilon}_t = e_t - (I_{n+1} - \hat{\Psi}_{11} L - \cdots - \hat{\Psi}_{p1} L^p)[z_t'(\hat{\theta} - \theta), 0]' \) and \( L \) being the lag operator. Although \( \hat{u}_{1t} \) includes an estimation error, its effect is asymptotically negligible. In fact, we can show that for \( j = -p, \cdots, p \),
\[ \frac{1}{T} \sum_{1 \leq t \leq T} \hat{u}_{1t} \hat{u}_{1t-j} = \frac{1}{T} \sum_{1 \leq t \leq T} u_{1t} u_{1t-j} + O_p \left( \frac{1}{T} \right), \]
\[ \frac{1}{T} \sum_{1 \leq t \leq T} \hat{u}_{1t} \hat{u}_{2t-j} = \frac{1}{T} \sum_{1 \leq t \leq T} u_{1t} u_{2t-j} + O_p \left( \frac{1}{T} \right) \]
while for \( j \geq 0 \),
\[ \frac{1}{\sqrt{T}} \sum_{1 \leq t \leq T} \hat{u}_{t-j} \hat{e}_t' = \frac{1}{\sqrt{T}} \sum_{1 \leq t \leq T} u_{t-j} e_t' + O_p \left( \frac{1}{\sqrt{T}} \right). \]
by the asymptotic technique explained in, for example, Chapters 17–19 in Hamilton (1994). If the evidence of Granger non-causality is observed by tests based on (6), we can expect the finite sample efficiency gain by excluding the leads of \( \Delta x_t \) from (3) and estimating (5).

We may also consider verifying condition (4) by investigating whether or not the regression error from (5) is serially uncorrelated. For this purpose, the portmanteau tests are available as explained in Lütkepohl (1993).
To demonstrate the case where the model can be expressed as (5), we consider the following case:

\[ u_{1t} = \sum_{j=0}^{\infty} \phi_j \varepsilon_{1t-j} \quad \text{and} \quad u_{2t} = \varepsilon_{2t} \quad \text{where} \quad \sum_{j=0}^{\infty} |\phi_j| < \infty \]

and \( \varepsilon_t = \begin{bmatrix} \varepsilon_{1t} \\ \varepsilon_{2t} \end{bmatrix} \sim iid \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{pmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{21} & \Sigma_{22} \end{pmatrix} \).

(7)

We then decompose \( \varepsilon_{1t} \) as

\[ \varepsilon_{1t} = \varepsilon_{1t} \cdot \varepsilon + \tilde{\varepsilon}_{2t} \]

where \( \varepsilon_{1t} \cdot \varepsilon = \varepsilon_{1t} - \sigma_{12} \Sigma_{22}^{-1} \varepsilon_{2t} \) and \( \tilde{\varepsilon}_{2t} = \sigma_{12} \Sigma_{22}^{-1} \varepsilon_{2t} \). Note that \( \varepsilon_{1t} \cdot \varepsilon \) is uncorrelated with all the leads and lags of \( \varepsilon_{2t} \) and \( \tilde{\varepsilon}_{2t} \). Using this decomposition, \( u_{1t} \) can be expressed as

\[ u_{1t} = \sum_{j=0}^{\infty} \phi_j \varepsilon_{1t-j} + \sum_{j=0}^{K} \phi_j \tilde{\varepsilon}_{2t-j} + \sum_{j=K+1}^{\infty} \phi_j \tilde{\varepsilon}_{2t-j} \]

\[ = v_t + \sum_{j=0}^{K} \Pi_j x_{t-j} + \sum_{j=K+1}^{\infty} \phi_j \tilde{\varepsilon}_{2t-j} \]

(9)

where \( \Pi_j = \phi_j \sigma_{12} \Sigma_{22}^{-1} \) and \( v_t = \sum_{j=0}^{\infty} \phi_j \varepsilon_{1t-j} \). Since \( E(\varepsilon_{2s} \varepsilon_{1t}) = 0 \) for all \( s \) and \( t \), it is evident that \( v_t \) is uncorrelated with \( \Delta x_{t-j} \) for all \( j \). The regression form in (5) is obtained by inserting (9) into (1).

To investigate the finite sample performance of the dynamic OLS estimator without leads, we conduct a Monte Carlo experiment. We consider the case of \( n = 1 \) and assume that \( u_{1t} \) follows a first-order autoregressive model with the AR coefficient \( \rho \), while \( u_{2t} \) is an iid sequence. We set \( T = 100, \sigma_{11} = \Sigma_{22} = 1, \sigma_{12} = \sigma_{21} = 0.4, 0.8, \) and \( \rho = 0.1, 0.5, 0.9 \). The computation was conducted by using the GAUSS matrix language, and the number of replications is 10,000 for all the cases. The simulation results are summarized in Table 1 (further simulation results are available from the author upon request).

For the choice of \( K \), we use the general-to-specific method by Ng and Perron (1995) with 1% and 5% significant levels and information criteria, i.e., the Akaike information criterion (AIC) and the Bayesian information criterion (BIC).

From Table 1, we observe that the dynamic OLS estimator without leads substantially outperforms that with leads and lags in all the cases. In particular, in terms of the MSE, the MSE of the DOLS estimator without leads are approximately half of that with leads and lags in many cases.

3 Conclusion

In this paper, we considered the role of leads of the first difference of the I(1) regressors in the dynamic OLS estimation. We demonstrated that leads are not necessary in cointegrating
regression models when the cointegrating regression error does not Granger-cause the first difference of the I(1) regressors. Based on a Monte Carlo simulation, we found that the dynamic OLS estimator without leads substantially outperforms that with leads and lags when leads are, in fact, unnecessary.
