<sup>1</sup>We are grateful to Alfonso Gambardella, Dietmar Harhoff, Emeric Henry, Nicola Lacetera, Bhaven Sampat, Carlos Serrano and John Turner for comments on an earlier draft of the paper. We also thank seminar participants at the NBER 2013 Summer Institute, the Hebrew University of Jerusalem, University of Toronto, University of Texas at Austin, Tilburg University, Hitotsubashi University and the Mines ParisTech. Deepa Agarwal, Faryal Ahmed, William Matcham and Jessica Zurawicki provided excellent research assistance. We are grateful for financial support from the Centre for Economic Policy at the London School of Economics and the Social Sciences and Humanities Research Council of Canada.

## **Abstract**

Cumulative innovation is central to economic growth. Do patent rights facilitate or impede such follow-on innovation? This paper studies the causal effect of removing patent protection through court invalidation on subsequent research related to the focal patent, as measured by later citations. We exploit random allocation of judges at the U.S. Court of Appeal for the Federal Circuit to control for the endogeneity of patent invalidation. We find that patent invalidation leads to a 50 percent increase in subsequent citations to the focal patent, on average, but the impact is highly heterogeneous. Patent rights appear to block follow-on innovation only in the technology fields of computers, electronics and medical instruments. The effect is entirely driven by invalidation of patents owned by large patentees that triggers more follow-on innovation by small firms.

# 1 Introduction

Cumulative research is a dominant feature of modern innovation. New genetically modified crops, memory chips and medical instruments are typically enhancements of prior generations of related technologies. Of course, cumulative innovation is not new. Economic historians have emphasized the role of path dependence in the development of technology, documenting how past successes and failures serve as ‘focusing devices’ that guide the direction of later technological inquiry (Rosenberg, 1976).<sup>1</sup> However, the increasing importance of basic science in shaping the direction of technological development has intensified this process.

Cumulative innovation, and the knowledge spillovers that underlie it, lie at the heart of the recent economic literature on innovation and growth. Leading examples of these endogenous growth models include Grossman and Helpman (1991), Aghion and Howitt (1992), Aghion, Harris and Vickers (1997) and Acemoglu and Akcigit (2012). At the same time, there is an extensive empirical literature showing that R&D creates knowledge spillovers, which increase both productivity growth and subsequent innovation.<sup>2</sup> This consensus on the centrality of knowledge spillovers to innovation, and innovation to growth, is the primary justification for government R&D-support policies.

In this paper we study how patent rights affect the process of cumulative innovation. The patent system is one of the main instruments governments use to increase R&D incentives, while at the same time promoting follow-on innovation.<sup>3</sup> However, there is growing concern among academic scholars and policy makers that patent rights are themselves becoming an impediment, rather than an incentive, to innovation. The increasing proliferation of patents, and the fragmentation of ownership rights among firms, are believed to raise transaction costs,

---

<sup>1</sup>This cumulative feature is reinforced by the constraints imposed by the prevailing stock of scientific knowledge on the feasible avenues for technology development (Mokyr, 2002). This is not say that science dictates only one path for the development of technology at any point in time. Recent theoretical work emphasizes the role of diverse research approaches in technological development (Acemoglu, 2012).

<sup>2</sup>For a recent survey of the literature, see Jones (2005). In a recent paper, Bloom, Schankerman and van Reenen (2013) show that R&D also creates negative (pecuniary) externalities through product market rivalry which can lead to over-investment in R&D. But their empirical results confirm that positive externalities dominate, with social returns to R&D exceeding private returns, at least on average.

<sup>3</sup>Specifically, the disclosure provision in patent law (35 U.S.C. Section 112) requires the patent applicant to describe the invention in order to promote information diffusion and ‘enable’ development of follow-on improvements of the original invention.

constrain the freedom of action to conduct R&D, and expose firms to ex-post holdup through patent litigation (Heller and Eisenberg, 1998; Bessen and Maskin, 2009). In the extreme case where bargaining failure in patent licensing occurs, follow-on innovation can be blocked entirely. These issues are particularly acute in ‘complex technology’ industries where innovation is highly cumulative and requires the input of a large number of patented components held by diverse firms. These dangers have been prominently voiced in public debates on patent policy in the United States (National Research Council, 2004; Federal Trade Commission, 2011) and recent decisions by the Supreme Court (e.g., *eBay Inc. v. MercExchange, L.L.C.*, 547 U.S. 338, 2006).

Economic research on the impact of patent rights on cumulative innovation has been primarily theoretical (for an good overview see Scotchmer, 2004). The main conclusion from these studies is that anything can happen – patent rights may impede, have no effect, or even facilitate subsequent technological development. It depends critically on assumptions about the bargaining environment and contracting efficiency between different generations of innovators. In an early contribution, Kitch (1977) argues that patents enable an upstream inventor to organize investment in follow-on innovation more efficiently and to mitigate rent dissipation from downstream patent races that would otherwise ensue. This ‘prospecting theory’ suggests that patent rights facilitate cumulative innovation. Green and Scotchmer (1995) show that upstream patent rights will not impede value-enhancing, follow-on innovation as long as bargaining between the parties is efficient. This work is important because it focuses our attention on bargaining failure as the source of any blocking effect patent rights might create. Finally, a number of papers have shown how patent rights can block innovation when bargaining failure occurs. This can arise from asymmetric information (Bessen and Maskin, 2009), or coordination failures when downstream innovators need to license multiple upstream patents (Shapiro, 2001; Galasso and Schankerman, 2010).

This diversity of theoretical conclusions highlights the need for empirical research. It is important not only to establish whether patent rights block subsequent innovation, but also how this process influences the ‘industrial organization’ of innovation. For example, does such blockage occur between all types of upstream and downstream firms, or is the problem concentrated among specific subsets of innovating firms? The issue is also relevant for management research because understanding how patents can be a source of competitive advantage is crucial

for developing effective intellectual property strategies.

There are two empirical challenges in studying the effect of patents on cumulative innovation. First, cumulativeness is difficult to measure directly. In this paper we follow the large empirical literature that uses citations by later patents as a way to trace knowledge spillovers (for a survey, see Griliches, 1992). While not perfect, this is the only feasible approach if one wants to study the impact of patent rights across diverse technology fields as we do in this paper. The second problem in identifying the causal effect of patent rights on later innovation is the endogeneity of patent protection. For example, technologies with greater commercial potential are both more likely to be protected by patents and to be an attractive target for follow-on innovation.

In important, and closely related papers, Murray and Stern (2007) and Williams (2013) provide the first causal evidence that intellectual property rights block later research in the biomedical field. Murray and Stern exploit patent-paper pairs to study how citations to scientific papers are affected when a patent is granted on the associated invention. Williams studies the impact of intellectual property on genes sequenced by the private firm Celera on subsequent human genome research and product development. Interestingly, both papers find roughly similar magnitudes – property rights appear to cause about a 20-40 percent reduction in follow-on research. These important studies focus on very specific (albeit significant) innovations in human genome and biomedical research. It is hard to know whether their conclusions generalize to other industries, and whether the effect varies across different types of patentees and later innovators. Understanding how the blocking effect of patents varies across technology fields and patent owners is essential for thinking about how best to design the strength and scope of patent protection.

In this paper we adopt a novel identification strategy to estimate the causal effect of patent protection on cumulative innovation. We use the patent invalidity decisions of the U.S. Court of Appeal for the Federal Circuit, which was established in 1982 and has exclusive jurisdiction in appellate cases involving patents. It is a fortunate institutional fact that judges are assigned to patent cases through a computer program that *randomly* generates three-judge panels, with decisions governed by majority rule. We exploit this random allocation of judges, together with variation in their propensity to invalidate patents, to construct an instrumental

variable which addresses the potential endogeneity of invalidity decisions. Because patents constitute prior art, later applicants are still required to cite patents when relevant even if they have been invalidated and thus put into the public domain. This allows us to examine how invalidation of a patent affects the rate of subsequent citations to that patent.

Patents that reach the Federal Circuit are a selective sample of highly valuable patents. To cite one example, in August 2006 the Federal Circuit invalidated one of Pfizer's key patents required for the production of the cholesterol-lowering drug Lipitor, the largest-selling drug in the world. Our reliance on privately valuable patents to estimate the effect of patent rights on cumulative innovation is similar to Azoulay, Graff Zivin and Wang (2007) who rely on the death of superstar scientists to estimate the magnitude of knowledge spillovers. It is reasonable to start by analyzing 'superstar' patents rather than a random sample of patents, not least because we know that the distribution of patent values is highly skewed (Schankerman and Pakes, 1986) and policy should be most concerned about the potential blocking of later innovation that builds on these valuable patents, where potential welfare costs are likely to be larger.

There are three main empirical findings in the paper. First, using the substantial heterogeneity in judges tendency to invalidate patents to control for endogeneity of the court decision, we find that patent invalidation leads to about a 50 percent increase in subsequent citations to the focal patent, *on average*. This finding is robust to a variety of alternative specifications and controls. Moreover, we show that this impact begins only after about two years following the court decision, which is consistent with the onset on follow-on innovation (rather than simply being a publicity effect from the court's decision).

Second, we find that the impact of patent invalidation on subsequent innovation is highly heterogeneous. For most patents, the marginal treatment effect of invalidation is not statistically different from zero. The positive impact of invalidation on citations is concentrated on a small subset of patents which have unobservable characteristics that are associated with a lower probability of invalidity (i.e., stronger patents). There is large variation across broad technology fields in the impact of patent invalidation and the effect is concentrated in fields that are characterized by two features: complex technology and high fragmentation of patent ownership. This finding is consistent with predictions of the theoretical models that emphasize

bargaining failure in licensing as the source of blockage. Patent invalidation has a significant impact on cumulative innovation only in the fields of computers and communications, electronics, and medical instruments (including biotechnology). However, we find no effect in the chemical, pharmaceutical, or mechanical technology field.

Lastly, we show that patent rights block later innovation in a very specific way. There is no statistically significant effect of patent rights on later citations when the invalidated patents are owned by small or medium sized firms. The impact is entirely driven by the invalidation of patents owned by *large* firms, which increases the number of *small* innovators subsequently citing the focal patent. This result suggests that bargaining failure among upstream and downstream innovators is not widespread, but is concentrated in cases involving large patentees and small downstream innovators. In this sense, patent rights held by large firms appear to impede the ‘democratization of innovation’.

The paper is organized as follows. In Section 2 we present a simple model to characterize the conditions under which patents facilitate, block or have no effect on follow-on innovation. Section 3 describes the data set. In Section 4 we develop the baseline econometric model for estimating the causal effect of patent rights and present the empirical results. In Section 5 we extend the analysis to allow for heterogenous marginal treatment effects, and empirically link them to characteristics of the patent case. Section 6 shows how the effect of patent invalidation depends on the characteristics of the patentee and later citing innovators. In addition, we decompose the overall effect into an extensive margin (number of later citing firms) and an intensive margin (number of later citing patents per firm). Section 7 discusses the interpretation and implications of the empirical findings. Section 8 examines the impact of invalidation on self-citations. We conclude with a brief summary of findings.

## 2 Analytical Framework

The granting of patent rights involves a basic trade-off between ex ante incentives and ex post efficiency. The market power conferred by a patent increases innovation incentives, but also reduces total surplus due to higher prices. This trade-off is well understood in the innovation literature. However, patents can also create a dynamic cost by blocking valuable sequential innovation, in cases where the second generation firm requires a license on the earlier technology

and the bargaining between the two parties fails. In this section we present a simple analytical framework that characterizes the conditions under which patents are likely to block, facilitate or have no effect, on follow-on investment, and we use the framework for organizing the different theoretical models in the literature.

There are two firms,  $x$  and  $y$ . Firm  $x$  produces technology  $x$  and firm  $y$  has an idea for a downstream technology  $y$ . To develop the idea and obtain a patent, firm  $y$  needs to sustain a cost  $c$ . We assume that, if technology  $x$  is patented, technology  $y$  can be sold only if the two firms sign a licensing deal.<sup>4</sup> Let  $\pi_x(x, 0)$  denote the profits firm  $x$  makes if  $x$  is protected by a patent and there is no licensing to firm  $y$ , and  $\pi_y(0, y)$  be the profits firm  $y$  makes when  $x$  is not protected by a patent. If there is a patent on  $x$  and licensing takes place, we let  $\pi_y(x, y)$  and  $\pi_x(x, y)$  denote the profits of the two firms (net of licensing fees) and  $\Pi(x, y) = \pi_y(x, y) + \pi_x(x, y)$  be the joint surplus.

There are three inequalities that determine downstream innovation incentives:

$$\pi_y(x, y) - c \geq 0 \tag{1}$$

$$\pi_y(0, y) - c \geq 0 \tag{2}$$

$$\Pi(x, y) - \pi_x(x, 0) - c \geq 0. \tag{3}$$

Inequalities (1) and (2) show the conditions to have innovation by firm  $y$  when technology  $x$  is patented and when it is not, respectively. Inequality (3) shows the condition required to have licensing by  $x$  to  $y$ . The maximum profits that firm  $x$  can obtain from licensing is  $\Pi(x, y) - c$  and this needs to be larger than  $\pi_x(x, 0)$  for licensing to be profitable.

Notice that the difference between total profits with and without technology  $y$ ,  $\Pi(x, y) - \pi_x(x, 0)$ , is increasing in the degree of complementarity between the innovations  $x$  and  $y$ . If  $x$  and  $y$  are perfect complements,  $\pi_x(x, 0) = 0$ . In the case of perfect substitutes  $\Pi(x, y) = \pi_x(x, 0)$  and follow-on innovation will be blocked for any  $c > 0$ . More generally, for given values of  $\pi_y(x, y)$  and  $\pi_y(0, y)$ , an increase in the degree of complementarity expands the range of cost

---

<sup>4</sup>This is the case when technology  $y$  is a patentable "new and useful improvement" of technology  $x$  ( 35 U.S.C. 101). If the downstream invention reflects a large enough innovative step, it may be patentable and not require a license from the upstream patentee. Nevertheless, as long as firm  $y$  (at the time of her R&D investment) assigns some positive probability to needing such a license, the presence of an upstream patent will affect her innovation incentives.

parameters,  $c$ , under which follow-on innovation takes place. Thus (3) implies that, when  $x$  is patented, sequential innovation does not take place when the substitutability between  $x$  and  $y$  is high enough – i.e., when the business stealing effect of innovation is strong.

Building on this simple framework, we now contrast the different classes of models that have emerged in the innovation literature.

*Positive impact of patents on follow-on innovation*

Using (1)-(3), a patent on  $x$  has a positive impact on downstream innovation if

$$\pi_y(0, y) < c \leq \min\{\pi_y(x, y), \Pi(x, y) - \pi_x(x, 0)\}.$$

This condition is implicitly assumed in Kitch (1977), the first paper to point out that upstream patents may be beneficial for downstream innovation. He describes an environment in which, in the absence of an upstream patent, development of technology improvements is impeded by coordination failures and free riding among downstream innovators and thus  $\pi_y(0, y) - c < 0$ . A patent on technology  $x$  allows the upstream firm to act as a gatekeeper and coordinate downstream investments. This has a positive effect on joint surplus,  $\Pi(x, y) - c - \pi_x(x, 0) \geq 0$ , and firm  $y$ 's incentive to innovate,  $\pi_y(x, y) - c \geq 0$ .<sup>5</sup>

*No effect of patents on follow-on innovation*

A patent on technology  $x$  has no effect on subsequent innovation if

$$\min\{\pi_y(x, y), \Pi(x, y) - \pi_x(x, 0), \pi_y(0, y)\} \geq c.$$

This condition is satisfied in the influential paper by Green and Scotchmer (1995) in which downstream innovations are joint surplus enhancing,  $\Pi(x, y) - c - \pi_x(x, 0) \geq 0$ , and ex-ante contracting guarantees that the downstream innovation is developed independently of the presence of a patent on technology  $x$  (i.e. both  $\pi_y(0, y) - c \geq 0$  and  $\pi_y(x, y) - c \geq 0$ ). They allow the profits of the two parties to depend on the length and breadth of the patent and these variables affect the incentives of firm  $x$  to develop the upstream technology, but once  $x$  has been developed frictionless bargaining ensures that efficient downstream investment takes

---

<sup>5</sup> Another example is the model by Arora (1995) in which development of downstream technology requires transfer of tacit know-how from firm  $x$  to firm  $y$ . Because it is difficult to contract on tacit knowledge, transfer only occurs when bundled with patent  $x$  in a licensing contract.

place.<sup>6</sup>

*Negative effect of patents on follow-on innovation*

A patent on technology  $x$  has a negative effect on subsequent innovation if

$$\min\{\pi_y(x, y), \Pi(x, y) - \pi_x(x, 0)\} < c \leq \pi_y(0, y).$$

This condition is typically satisfied when there are frictions in the licensing process, and these can arise for several reasons. First, ex ante licensing may not take place in the presence of asymmetric information between the upstream and downstream innovators, as shown by Bessen and Maskin (2009) and Comino, Manenti and Nicolò (2011). Moreover, Priest and Klein (1984) and Galasso (2012) show that licensing breakdown may occur even with symmetric information when parties have divergent expectations about the profitability of the technology. The risk of hold up, high litigation costs and pro-patent remedy rules all reduce the expected value of ex post licensing profits for the downstream innovator  $\pi_y(x, y)$  and thus dilute his incentives to develop  $y$ ,  $\pi_y(x, y)$ .<sup>7</sup>

Second, bargaining failure can arise when patent rights are fragmented and a downstream firm requires licenses from many different patentees to conduct its research. In this case, uncoordinated bargaining among the parties leads to ‘royalty stacking’ that reduces the licensee’s profit and, in extreme cases, can actually block downstream development if  $\pi_y(x, y) - c < 0$  (Heller and Eisenberg, 1998; Shapiro, 2001; Lemley and Shapiro, 2007; Galasso and Schankerman, 2010).<sup>8</sup> The condition is also satisfied in recent papers by Aghion, Dewatripont and Stein

<sup>6</sup>Even though blockage does not occur in this framework, Koo and Wright (2010) show that patent rights can induce the downstream innovator to delay development.

<sup>7</sup>To see this, assume that profits of firm  $y$  are private information. Firm  $x$  believes firm  $y$  profits are equal to  $\bar{\pi}$  with probability  $\rho$  and equal to 0 with probability  $1 - \rho$  with  $\rho\bar{\pi} < c < \bar{\pi}$ . If  $\rho$  is small enough, the expected joint profits  $\Pi(x, y)$  are small and ex ante licensing will not take place. In the absence of ex ante licensing, firm  $y$  will invest only if profits are  $\bar{\pi}$ . If investment takes place, firm  $x$  will learn that firm  $y$  profits are equal to  $\bar{\pi}$ . Because after investment the cost  $c$  is sunk and firm  $x$  has learned that  $y$  has high profits, firm  $x$  will expropriate all the profits of  $y$ . This ex post expropriation will induce  $y$  not to invest in innovation.

<sup>8</sup>For example, in the setting of Lemley and Shapiro (2007), the downstream firm’s profit is

$$\pi_y(x, y, N, \theta) = P(q)q - (c + r_x(\theta) + \sum_{i=1}^N r_i(\theta))q$$

where  $P(q)$  is the demand function for the downstream product,  $r_x(\theta)$  is the royalty per unit of output paid to firm  $x$ ,  $r_i(\theta)$  are royalty rates paid to  $N$  other patentees with  $1 \leq i \leq N$ ,  $\theta$  is the degree of complementarity among the  $N + 1$  patents and  $r'(\theta) > 0$  for each patentee. Because of uncoordinated bargaining,  $\pi_y(x, y, N, \theta)$  decreases in  $N$  and  $\theta$  and downstream innovation does not take place when  $N$  and  $\theta$  are large enough.

(2008) and Murray et. al. (2008), which argue that academic research on base technologies (e.g. research tools) can increase the profitability of downstream research because of the open science regime, and lower wages of scientists, in academia.<sup>9</sup>

To summarize, this framework suggests that blockage is more likely when: 1) the degree of asymmetric information is high, 2) the downstream innovator needs to bargain with multiple patentees, and 3) there is a high degree of substitutability between the upstream and downstream innovations. The empirical literature has documented that uncoordinated bargaining and asymmetric information are more likely when patent ownership is fragmented (Ziedonis, 2004) and in complex technology areas where downstream innovation builds on numerous patented inputs (Cohen, Nelson and Walsh, 2000). In the empirical analysis in Section 5, we examine how these two features – fragmentation and complexity – influence the extent to which patent rights block cumulative innovation.<sup>10</sup>

### 3 Description of the Data

The empirical work is based on two data sets: the decisions of the Court of Appeal for the Federal Circuit, and the U.S. Patent and Trademark Office (USPTO) patent dataset.

The Federal Circuit has exclusive jurisdiction over appeals in cases involving patents and claims against the federal government in a variety of subject matter.<sup>11</sup> The Federal Circuit consists of twelve judges appointed for life by the president. Judges are assigned to patent cases through a computer program that randomly generates three-judge panels, subject to the judges' availability and the requirement that each judge deals with a representative cross section of

---

<sup>9</sup>For example, in Murray et. al. (2008), the payoff to the downstream innovator is  $\pi_y(x, y) = V - w$  when the upstream innovation is patented by a firm, where  $V$  is product market profits and  $w$  is the wage to the scientist. When upstream innovation is controlled by academia and unpatented, the downstream firm extracts  $\pi_y(0, y) = V + \psi - w$  where  $\psi > 0$  is the extra rent due to the absence of upstream patenting (and possibly lower wages). If  $\psi > c - \pi_y(x, y) > 0$ , downstream innovation takes place only when  $x$  is unpatented.

<sup>10</sup>While the empirical literature links bargaining failure with complexity and fragmentation of patent ownership, theoretically the relationship depends crucially on the degree of complementarity among the required patented inputs (Galasso and Schankerman, 2010). To our knowledge, a general bargaining framework that microfound this linkage remains to be developed.

<sup>11</sup>The Federal Circuit was established by the U.S. Congress on October 1, 1982. It merged the U.S. Court of Customs and Patent Appeals and the appellate division of the U.S. Court of Claims. The creation of this specialized court was proposed by the Commission on Revision of the Federal Court Appellate System (also known as the Hruska Commission) to bring greater uniformity in patent law and enforcement, and to reduce the caseload crisis in the federal courts of appeal.

the fields of law within the jurisdiction of the court (Fed. Cir. R. 47.2). Decisions are taken by majority rule. We obtain the full text of patent decisions by the Federal Circuit from the LexisNexis QuickLaw dataset. This contains a detailed description of the litigated dispute, the final decision reached by the court, and the jurisprudence used to reach the decision. Using keyword searches we identify each case involving issues of patent validity from the establishment of the court in 1982 until December 2008. For each case we record the following information: docket number, date of the decision, patent identification number, name of the three judges involved, name of the plaintiff, name of the defendant, and whether the patentee is the plaintiff or the defendant.

Information about each patent in the sample is obtained from the USPTO patent database. We also identified the patents citing the litigated patent from two sources: the USPTO citations data for sample patents granted in the period 1975-2010, and Google Patents for sample patents granted before 1975.

We use the number of citations by subsequent patents to the focal patent as a measure of cumulative innovation. Patent applicants are required to disclose known prior art that might affect the patentability of any claim (Code of Federal Regulations, Ch. 37, Section 1.36), and any willful violation of this duty can lead to the USPTO rendering the patent unenforceable due to ‘inequitable conduct’. Importantly for our purposes, the expiration or invalidation of a patent has no impact on its prior art status (35 U.S. Code, Section 102), so the requirement to cite it remains in place.

Citations have been widely used in the economics of innovation literature as a proxy for follow-on research. The only exception is the study by Williams (2013) which traces cumulative innovation by using citations to research as well as product development measures. Using product development information is clearly desirable, but it is only feasible in studies that focus on a specific technology as in her paper. Patent citations are the only practical measure of cumulative innovation for studies such as ours that cover a wide range of technology fields, but certain qualifications should be kept in mind. From an economic perspective, patent citations play two distinct roles: first, they indicate when the new invention builds on prior patents (and thus may need to license the upstream patent), and second, citations identify prior art that circumscribes the property rights that can be claimed in the new patent. Citations will under-

estimate the extent of cumulative innovation in cases where inventors develop improvements that are not patented (or patentable). But citations can also overestimate it, when they only indicate prior art that limits the claimed property rights but do not indicate that the inventor actually built on the prior patent. However, the fact that we use citations primarily as an endogenous outcome measure makes any measurement error less problematic.<sup>12 13</sup>

The main variables used in the empirical analysis are described below.

**PostCites:** citations received from patents of other assignees in a five year window after the Federal Circuit decision. This is our primary measure of cumulative innovation. Because of granting delays, we date the citing patents using their application year rather than grant year.

**PostSelfCites:** citations received from patents owned by the same patentee as the focal (litigated) patent in a five year window after the Federal Circuit decision. We will use this alternative dependent variable to explore the effect of invalidity on the patentee’s research trajectory.

**Invalidated:** a dummy variable equal to one if the Federal Circuit invalidates at least one claim of the patent. This is the main explanatory variable of interest, and represents the removal of patent rights.<sup>14</sup>

**PreCites:** citations received from patents of other assignees applied for in the period between the grant of the patent and the Federal Circuit decision

**PreSelfCites:** citations received from patents of the same patentee as the focal patent

---

<sup>12</sup>Not all citations originate from applicants; some are added by USPTO examiners during the granting process. Because the USPTO began reporting examiner and applicant citations separately only for patents granted after 2001 (Alcacer and Gittleman, 2006), we cannot distinguish between the two types of citations for most of the patents in our data (only 4 percent of our sample patents were granted after 2001). For our purposes of tracing cumulative innovation, examiner-added citations may introduce measurement error if they do not reflect prior art that the new patent applicant is aware of when she undertook her R&D. However, examiner citations may reduce measurement error if applicants strategically withhold citations.

<sup>13</sup>By measuring cumulative innovation with patent citations, we only consider follow-on technologies that pass the novelty and non-obviousness requirements for patentability. This helps mitigate the concern that subsequent innovation is not merely replicating the invalidated technology.

<sup>14</sup>We experimented with an alternative definition of invalidation as whenever Claim 1 of the patent (typically representing the primary claim) is invalidated. About 40 percent of patents are invalidated on our baseline measure, and 33 percent using the alternative definition. The empirical results are very similar with both measures. In the empirical results reported below we will also use the fraction of invalidated claims as an alternative explanatory variable.

applied for in the period between the grant of the patent and the Federal Circuit decision

**Claims:** total number of claims listed in the patent document

**Technology field:** dummy variables for the six technology classes in Hall, Jaffe and Tratjenberg (2001) – chemicals, computers and communications, drugs and medical, electrical and electronics, mechanicals, and others. We will also employ a narrower definition based on the 36 two-digit subcategories.

Finally, we construct a set of dummy variables for the year when the Federal Circuit decision is issued and for the age of the patent.

The final dataset contains 1357 Federal Circuit patent validity decisions, covering 1258 distinct patents.<sup>15</sup> Table 1 provides some summary statistics. The Federal Circuit invalidates in 39 percent of the cases, and in 61 percent of those decisions the entire patent is invalidated. Figure 1 shows substantial variation in the age distribution of litigated patents (at the time of the Federal Circuit decision). Note that lengthy lower court trials in some cases lead to Federal Circuit decisions occurring after the patent has expired.

Patents involved in Federal Circuit cases are a selected sample of highly valuable ‘superstar’ patents. For example, in January 2005 the Federal Circuit invalidated the patent for the once-a-week version of Merck’s Fosamax, the leading osteoporosis drug in the market at that time. This can be seen in Table 2, which compares characteristics of the patents in the Federal Circuit to patents litigated in lower courts but not appealed, as well as to the universe of patents granted by the USPTO.<sup>16</sup> Drugs and medical patents are more heavily represented in the litigated and Federal Circuit samples than in the overall sample. This is consistent with survey evidence that patent rights are most important in that sector (Levin et. al., 1987). We also see that the number of claims, citations per claim, and conventional measures of patent generality and originality (as defined by Hall, Jaffe and Tratjenberg, 2001) are all higher for litigated than other patents, and even higher for cases appealed to the Federal Circuit. Equality

---

<sup>15</sup>This is because there are multi-patent cases and some patents are litigated more than once. Our sample size and mean invalidation rate are similar to an earlier study using Federal Circuit cases (Henry and Turner, 2006).

<sup>16</sup>To perform this comparison, we use litigation data from Lanjouw and Schankerman (2001) and the NBER patent dataset. Because the lower court litigation data are available only up to 1999, we focus on patents granted during 1980-1999. Of the 1,816,863 patents granted by the USPTO in this period, 8,093 are litigated (0.45 percent) and 877 are involved in Federal Circuit invalidity decisions (0.05 percent).

of the means is strongly rejected for all four variables (p-values<0.01). The mean number of claims and citations per claim for patents litigated only at lower courts are different from those appealed to the Federal Circuit (p-values <0.01).

## 4 Estimating the Impact of Patent Rights

### Baseline Specification and Identification Strategy

The final dataset is a *cross section* where the unit of observation is a Federal Circuit case involving patent  $p$ .<sup>17</sup> Our main empirical specification is

$$\begin{aligned} \log(PostCites_p + 1) = & \beta Invalidated_p + \lambda_1 \log(PreCites_p + 1) \\ & + \lambda_2 \log(PreSelfCites_p + 1) + \lambda_3 \log(Claims_p) + Age_p + Year_p + Tech_p + \varepsilon_p \end{aligned} \quad (4)$$

The coefficient  $\beta$  captures the effect of invalidation on the subsequent (non-self) citations received by a patent. When  $\beta < 0$  invalidation reduces later citations, indicating that patent rights have a positive impact on cumulative innovation. A finding of  $\beta = 0$  would indicate that patents do not block follow-on innovation. When  $\beta > 0$  we would conclude that patents block subsequent innovation.<sup>18</sup>

To control for heterogeneity in the value that the patent has for the patentee and follow on inventors, we include the number of claims and the number of external and self citations received prior to the Federal Circuit decision (*PreCites* and *PreSelfCites*, respectively) as covariates in the regression. We also include age, decision year and technology field dummies to control for additional heterogeneity that may be correlated with the court decision and later citations. We report heteroskedasticity-robust standard errors. Because some patents are litigated more than once and some cases involve multiple patents, we also confirm significance using standard errors clustered at the patent or case level.

---

<sup>17</sup>Even though we have some cases of the same patent litigated more than once, we use the subscript  $p$  to denote the patent case to emphasize that our sample is a cross section.

<sup>18</sup>While a variety of econometric models can be used to estimate the correlation between citations and the Federal Circuit invalidity decisions, the cross sectional specification is preferable for two reasons. First, the cross section allows us to use (time invariant) judge allocations as instruments for patent invalidity decision. Second, this specification allows us to examine heterogeneity in the effect of patent invalidation by estimating the Marginal Treatment Effect. Our specification is very similar to those employed in other studies where instrumental variables are used to examine heterogeneous causal effects. For example, Carneiro, Heckman and Vytlačil (2010) collapse a panel into a cross-section and use a time-invariant instrument to estimate heterogeneous effects.

The major empirical challenge is that the decision by the Federal Circuit to invalidate a patent is endogenous. For example, a positive shock to the value of the underlying technology may increase citations to a patent and, at the same time, induce the patentee to invest heavily in the case to avoid invalidation. This would generate a negative correlation between  $\varepsilon_p$  and  $Invalidated_p$  in equation (4) and a downward bias to the OLS estimate of  $\beta$ .<sup>19</sup> To address potential endogeneity, we need an instrument that affects the likelihood of patent invalidation but does not belong directly in the citations equation. To construct such an instrument, we exploit the fact that judges in the Federal Circuit are assigned to patent cases randomly by a computer program, subject to their availability and the requirement that each judge deals with a representative cross section of legal fields within the court’s jurisdiction (Fed. Cir. R. 47.2). However, randomization of judge panels does not ensure randomization of decisions, which can still arise because of information that becomes available during the appellate process that could also be correlated with future citations. The instrument we construct below takes this concern into account.<sup>20</sup>

Since its establishment in 1982, the Federal Circuit patent cases in our sample have involved a total of 51 distinct judges, including 22 non-appointed judges that filled in the vacancies during the Senate nomination process. Appendix Table A1 lists the (appointed) Federal Circuit judges in our sample, the number of decisions in which each judge was involved, and the percentage of cases in which each judge voted for patent invalidation.<sup>21</sup> There is substantial variation across judges in the propensity to vote for patent invalidity (which we refer to as judge ‘bias’), ranging from a low of 24.4 percent to a high of 76.2 percent.

Our instrumental variable, the Judges Invalidation Propensity ( $JIP$ ), is defined for each case involving patent  $p$  as

$$JIP_p = f_p^1 f_p^2 f_p^3 + f_p^1 f_p^2 (1 - f_p^3) + f_p^1 (1 - f_p^2) f_p^3 + (1 - f_p^1) f_p^2 f_p^3$$

---

<sup>19</sup>A downward bias could also arise if the existence of relevant prior art makes patent invalidation more likely and at same time reduces the propensity of later innovators to cite the focal patent.

<sup>20</sup>During the first few years of Federal Circuit court, the composition of panels took into account that judges formerly on the Court of Customs and Patent Appeals had greater experience in patent law, but from the beginning the court ensured a blind assignment of cases to panels (Nies, 1992).

<sup>21</sup>The sources for nomination and active service years are <http://www.cafc.uscourts.gov/> and Wikipedia.

where  $f_p^1, f_p^2, f_p^3$  are the fractions of votes in favour of invalidity by each of the three judges assigned to the case calculated for all decisions *excluding* the case involving patent  $p$ . In other words, the decision for the focal patent does not enter into the computation of the instrument for that decision. In a simple setting where each judge  $i$  votes in favor of invalidity with probability  $f_p^i$ ,  $JIP$  captures the probability of invalidation by the three judge panel (decision by majority rule). In an Appendix we show that, under plausible assumptions on the dispersion of private information,  $JIP$  provides a consistent estimate of the probability of invalidation in a strategic voting model (a la Feddersen and Pesendorfer, 1996) where the thresholds of reasonable doubt differ across judges.

There are two important features of  $JIP$  that make it a valid instrumental variable. First, the random allocation of judges assures that judges with high propensity to invalidate are not assigned to cases because of unobservable characteristics that are correlated with citations. Second, any additional effect that case-specific unobservables may have on the decision to invalidate patent  $p$  (e.g., information revealed during the litigation process) is removed by dropping the decision on patent  $p$  from the construction of the instrument for patent  $p$ .<sup>22</sup>

Figure 2 plots the distribution of the  $JIP$  index. There is substantial variation –  $JIP$  has a mean of 0.34, but ranges from 0.16 to 0.58. Part of the variation in  $JIP$  may reflect year effects because ‘biased’ judges may be active only for a limited period of time. To address this, we regressed  $JIP$  against a set year fixed effects and find that year effects explain only about 11 percent of the variation.

Our identification strategy is similar to the one employed by Doyle (2007, 2008), who uses differences in the placement tendency of child protection investigators as an instrument

---

<sup>22</sup>The propensity to invalidate of the panel of judges may induce the litigating parties to settle the case. Theoretical models of patent litigation typically predict that settlement is more likely for low value patents, especially in the presence of large judge bias, either pro- or anti-patent (Galasso and Schankerman, 2010). In our setting, this suggests that the value of patents that reach final adjudication by judge panels with extreme values of  $JIP$  will be higher than the value of patents in cases decided by panels with intermediate values of  $JIP$ . If patent value is correlated with post-decision citation, this selection would introduce bias to our estimates. The actual impact of this selection bias is ambiguous, however, as it would depend on the relative stakes and bargaining power of the patentee and the challenger.

Empirically, settlement at the appellate level is quite infrequent. Aggregate figures available on the Federal Circuit website show that in the period 1997-2007 about 80 percent of the filed cases were terminated with a panel decision. A possible reason for the low settlement rate is that the identity of judges is revealed to the disputants only after all briefs have been filed, and most of legal costs have already been sunk.

to identify the effects of foster care on long term outcomes.<sup>23</sup> The main difference between the two approaches is that our *JIP* index is constructed at the (three judge) panel level. The basic assumption behind this measure is that judges differ in their propensity to invalidate patents. To check this, we construct a dataset with judge-vote as the unit of observation and regress the *Invalidated* dummy against judge fixed effects and controls for the number of claims, external and self-citations prior to the court decision, plus decision year, technology class and patent age fixed effects. We strongly reject the hypothesis that the fixed effects for the different judges are the same (p-value<0.01). The distribution of estimated fixed effects is plotted in Appendix Figure A1 and shows substantial variation in their propensity to invalidate.<sup>24</sup>

To provide additional evidence that the estimated variation is inconsistent with judges having identical voting propensities, we construct a counterfactual where judges vote according to the same random process. Specifically, we generate a simulated judge vote that takes into account the effect of observable patent characteristics on the probability of invalidation.<sup>25</sup> We use the simulated vote to estimate judge fixed effects and find that they are not statistically significant (p-value=0.66). In Figure A1 we compare the distribution of these fixed effects from simulated votes with the (statistically significant) fixed effects estimated using actual voting behavior. The difference between the two distributions is striking: the variance of the Federal Circuit fixed effects is much larger than the one we would observe if judges were voting following the same random process.

Our main estimation approach, following Galasso, Schankerman and Serrano (2013),

---

<sup>23</sup>There are few others recent papers that exploit heterogeneity in the decision of judges and other experts for identification, notably Li (2012) and Di Tella and Schargrodsky (2013).

<sup>24</sup>A natural alternative to *JIP* is to exploit judge fixed effects. There are two reasons why *JIP* is more compelling. First, *JIP* takes into account that the invalidity decision is taken by a panel of judges, so the *impact* of each judge's invalidity propensity depends on the other members of the panel. Second, in *JIP* the dependence on the endogenous regressor for observation  $i$  is removed by dropping that observation in the construction of the instrument (as in the Jackknife IV of Angrist et. al., 1999).

<sup>25</sup>To construct the simulated votes, we use the following procedure. First, we regress the votes of each judge on observable characteristics of the cases, without including judge fixed effects, and then construct the predicted probability of an invalidity vote for each judge  $j$  for patent  $p$ , based on these characteristics,  $\phi_{jp}$ , and the regression residuals,  $e_{jp}$ . Second, we add to the probability  $\phi_{jp}$  a random draw  $\omega_{jp}$  from a normal distribution with mean and standard deviation equal to the mean and standard deviation of the distribution of the regression residuals. Finally, the simulated invalidity vote for judge  $j$  for patent  $p$  is set equal to one if the sum of the predicted invalidity and the random draw ( $\phi_{jp} + \omega_{jp}$ ) is above one. We obtain very similar results using different thresholds.

instruments the invalidated dummy with the predicted probability of invalidation obtained from the probit model  $\widehat{P} = P(JIP, X)$ . When the endogenous regressor is a dummy, this estimator is asymptotically efficient in the class of estimators where instruments are a function of  $JIP$  and other covariates (Wooldridge, 2002). Specifically, we estimate the following two-stage model

$$Invalidated_p = \alpha \widehat{P}_p + \theta X_p + u_p \quad (5)$$

$$\log(PostCites_p + 1) = \beta \widehat{Invalidated}_p + \gamma X_p + \varepsilon_p \quad (6)$$

where the set of controls  $X$  is the same in both stages.

### Judge Panels and Patent Invalidation

Table 3 examines the relationship between patent invalidation and the composition of judge panels. We begin in column 1 by using judge fixed effects to capture variation in judge ‘bias’ (as in Abrams, Bertrand and Mullainathan, 2013). Regressing *Invalidity* on these dummies and other controls, we strongly reject equality of judge effects, confirming heterogeneity in the propensity to invalidate. The judge fixed effects explain about 6.5 percent of the variation in Federal Circuit invalidity decisions.

As indicated earlier, using judge fixed effects in our context neglects the fact that decisions are taken by three-judge panels. To take this into account, in columns 2 to 4 we report probit regression models of the invalidity dummy against the  $JIP$  index. The estimated marginal effect in column 2 indicates that a one standard deviation increase in  $JIP$  is associated with an increase of about 7 percentage points in the likelihood of invalidation. The results are similar when we add a set of controls for patent characteristics (column 3) – a one standard deviation change in  $JIP$  is associated with an increase of about 5 percentage points in the probability of invalidation (the implied elasticity is 1.07). We also find that the patents that are more heavily cited before the court decision are less likely to be invalidated. Interestingly, there are no significant differences across technology fields in the likelihood of invalidation (joint test has a p-value=0.17).

In column 4 we use an alternative measure of invalidation – the fraction of invalidated claims. Here too we find a positive and statistically significant association between the degree

of patent invalidation and the *JIP* index, with a one standard deviation increase in *JIP* being associated with an increase in the fraction of invalidated claims of about 3 percentage points.

Finally, in column 5 we present the result of an OLS regression with *JIP* as dependent variable that provides support to the randomization of judges to cases. The number of claims of the litigated patent, the pre-Federal Circuit cites, the age of the patent and its technology class all appear uncorrelated to the panel propensity to invalidate patents. Only the year effects appear significantly correlated with *JIP*. The significance of the year effects arises mechanically because some of the ‘biased’ judges are active only for a fraction of our sample period.

We perform a variety of tests to confirm robustness of these findings (results not reported, for brevity). First, there is the concern that the invalidity decision may depend on whether patents have been invalidated by lower courts. To address this issue, we controlled for the lower court decision and find a positive correlation between the Federal Circuit and district court decisions. However, introducing this additional covariate has essentially no effect on the magnitude and statistical significance of the *JIP* coefficient. Second, invalidity decisions may also depend on characteristics of sub-technology fields not captured by our six broad technology field dummies. We re-estimate the probit regression controlling for more detailed technology field classifications using the 32 NBER technology sub-categories. The magnitude of the estimated *JIP* coefficient remains similar (1.262, p-value <0.01). In addition, we re-run the probit regression in column 3 separately for each of our six different technology fields. The magnitude and the statistical significance of the coefficients are very similar to the pooled data, indicating that the correlation between *JIP* and invalidity is comparable across technology classes. Finally, we obtained similar marginal effects using logit and linear probability models, and confirmed statistical significance using standard errors clustered at the patent or case level.

## **Patent Invalidation and Cumulative Innovation**

### **Baseline Specification**

In Table 4 we examine how patent invalidation affects the number of subsequent citations to the focal patent. We begin in column 1 by presenting the OLS estimate of the baseline specification relating external citations in a five year window after the court decision on the invalidity dummy and additional controls. There is no significant correlation between patent

invalidation and future citations. This result is not causal, however. As we argued above, there are reasons why we should expect unobservable factors to affect both the invalidity decision of the Federal Circuit and subsequent citations. This intuition is confirmed by a Rivers-Vuong test that provides strong evidence against the exogeneity of invalidation.<sup>26</sup>

To address the endogeneity concern, in column 2 we move to an IV specification and instrument the *Invalidated* dummy with *JIP*. The estimate shows a statistically significant, positive effect between citations and invalidation by the Federal Circuit. The substantial difference between OLS and IV estimates highlights the importance of controlling for the endogeneity of invalidation, and indicates a strong negative correlation between *Invalidated* and the disturbance in the citation equation,  $\varepsilon_p$  (inducing a large downward bias if we treat Federal Circuit invalidation as exogenous).

In column 3 we instrument the invalidated dummy with the predicted probability of invalidation obtained from the probit regression (rather than *JIP* itself) reported in column 3 of Table 3. This is more efficient as the endogenous regressor here is binary (Wooldridge, 2002), and as expected the first stage F-statistic increases from 17.4 to 94.8 when we replace *JIP* with the predicted probability from the probit. The estimated coefficient implies that patent invalidation (induced by being randomly allocated to a panel of judges with high propensity to invalidate) causes an increase in external citations of about 50 percent in the five years following Federal Circuit decision.<sup>27</sup>

In column 4 we examine the relationship between citations and the *fraction of claims* invalidated by the Federal Circuit. Because the endogenous regressor is a fraction, we cannot use the predicted probability of invalidation as an instrument, so we use *JIP* as the instrument. Not surprisingly, the first stage F-statistics is weaker in this more demanding specification, but we still find a positive effect of invalidation on subsequent citations received. The estimated

---

<sup>26</sup>Following Rivers and Vuong (1998), we regress *Invalidated* on *JIP* and the other controls in a linear probability model. We construct the residuals ( $\hat{v}$ ) for this model and then regress subsequent citations on *Invalidated*,  $\hat{v}$  and the other controls. The coefficient on  $\hat{v}$  is negative and highly significant (point estimate of -1.23, p-value<0.01).

<sup>27</sup>Because the specification relates log of cites to the dummy variable *Invalidated*, we compute the marginal effect as  $e^{0.41} - 1 = 0.50$ . This follows because in the semilogarithmic model  $\ln Y = \beta D$  where  $D$  is a dummy variable  $(Y_1 - Y_0)/Y_0 = e^\beta - 1$  where  $Y_1$  and  $Y_0$  are the values of the dependent variable when  $D$  is equal to one and zero respectively.

coefficient implies that a one standard deviation increase in the fraction of invalidated claims increases citations by 77 percent in the five year window after the court decision.

These instrumental variable regressions provide strong, causal evidence that the loss of patent rights increases subsequent citations to the patent. This evidence shows that, *at least on average*, patents block cumulative innovation. However, in the following sections we will show that this average effect is misleading because it hides the fact that the ‘blocking effect’ of patent rights is highly heterogenous. Moreover, we will reveal how the impact of patents varies with the characteristics of the patent, the patentee and the technology field.

### **Robustness and Extension**

In this section we describe a series of robustness checks on our main finding and two extensions of the empirical analysis. First, up to now we have treated an invalidation judgement as the final verdict. However, parties to the dispute have the right to appeal the decision of the Federal Circuit to the Supreme Court (which retains discretion over whether to hear the case). This means that invalidation of a patent by the Federal Circuit retains some uncertainty, so that downstream innovators whom the patent blocked might not respond until this uncertainty is removed. In our context, this is equivalent to saying that our key variable, *Invalidation*, contains some measurement error. In theory, any such error should be taken care of by our instrumental variable estimation. Nonetheless, as a further check we identified that the patent invalidity cases appealed to the Supreme Court in our data set.<sup>28</sup> We drop these cases and re-estimate the model (by IV). Our point estimate of the coefficient on patent invalidation is 0.394 (standard error of 0.197), which is very close to the baseline coefficient of 0.410.

Second, the baseline model incorporates fixed effects for six broad (one-digit) technology fields. We also estimate a specification which uses a more refined technology classification – 32 two-digit subcategories from the NBER. The point estimate of the coefficient on *Invalidation* is nearly double the baseline estimate but less precise, 0.915 (standard error of 0.422), and we cannot reject the null hypothesis that the two estimated coefficients are the same (p-value=0.11).<sup>29</sup>

---

<sup>28</sup>Only 23 Federal Circuit decisions were reviewed by the Supreme Court in the period 1982-2008 (Golden, 2009). Only 12 of these cases are in our dataset (the others involve issues other than patent validity).

<sup>29</sup>We retain the one-digit technology field dummies in the later empirical analysis (Section 6), where we investigate heterogeneity in the effect of patents on cumulative innovation. We do this because that analysis

Third, the baseline specification incorporates a full set of patent age fixed effects. However, the age distribution of citations may vary across technology fields (for evidence, see Jaffe and Trajtenberg, 2002). To allow for this, we extend the specification by including a full set of interactions between the technology field and age dummies. The estimated coefficient on *Invalidation* is 0.401 (standard error of 0.192), which is nearly identical to the baseline coefficient.

The fourth robustness check involves how to treat patents that receive no citations before the Federal Court decision (4 percent of the sample) and those that receive no cites in the five year widow after the decision (23 percent of the sample). In our baseline specification we ‘fix’ this problem by using  $\log(\text{PostCites} + 1)$ , which is common practice but may introduce bias. We re-estimate the baseline model adding dummy variables for patents that received no cites before the Federal Circuit decision and for patents that receive no cites after the decision. The results are robust – the point estimate on *Invalidation* is 0.449 (standard error of 0.167). We get similar results if we drop these patents from the sample entirely, as well as other approaches.<sup>30</sup>

Finally, there is a concern that some Federal Circuit decisions may involve rulings that limit the scope of patentable subject matter rather than simply assessing the validity of the focal patent. Such decisions could reduce subsequent citations for the entire technology field leading us to underestimate the true blocking effect of patent rights. To address this, we identified the most important Federal Circuit decisions that relate to patentable subject matter during our sample period (the main sources are Dolmeage, 2006 and Kappos et al, 2008).<sup>31</sup> Dropping

---

involves using smaller subsamples split along various dimensions. As a robustness check, we re-estimate all of those regressions using the more detailed, two-digit technology field dummies and obtain qualitatively (and in most cases, quantitatively) similar results, but the estimates are less precise.

<sup>30</sup>We get similar results if we use the number of citations without logarithmic transformation as the dependent variable. Finally, we also estimated a Poisson count model by instrumental variables (using the predicted probability of invalidation  $\hat{P}$  as the instrument). The point estimate is 0.638 (standard error of 0.321) which is larger than, but not statistically different from, the baseline coefficient. In the analysis that follows, we do not use the Poisson model because the econometric techniques that we will use to estimate the heterogenous effects of patent invalidation have only been developed for linear models.

<sup>31</sup>We obtained a list of 14 Federal Circuit decisions that are concentrated in the areas of software, business methods and biotechnologies, of which three are in our sample. There are very few cases in our sample because most of the key Federal Circuit decisions on patentable subject matter do not involve granted patents but only patent applications. Moreover, because of their importance, some of these decisions are decided ‘en banc’ by the entire court and not by a panel of three judges. Such special cases are also excluded from our sample.

those decisions and re-estimating the model we obtain coefficients that are nearly identical to the baseline estimates.

We turn now to extensions that have independent interest. In the first, we examine whether Federal Circuit invalidation has a smaller effect on older patents. Consider the extreme case where invalidation occurs after the patent has expired (there are such cases, as Figure 1 shows). Because the patent no longer has the power to block follow-on development, the invalidation decision should have no effect. More generally, for patents near statutory expiration we would expect to see less blocking effect, both because follow-on research is likely to have dissipated over time for old technologies and because the five year window after the invalidation decision will include years after expiration. Because of sample size we cannot estimate the invalidation effect separately for each patent age. As an alternative, we examine how the estimated effect changes as we successively drop older patents. Column 1 of Table 5 shows that the effect of invalidation is slightly larger when we drop the 44 observations where patents are litigated after expiration (age 20). Columns 2 and 3 show that the effect continues to rise as we drop patents older than 18 and 15, respectively. Compared to our baseline estimate, the effect of invalidation is 28 percentage points larger for patents that are invalidated during their first 15 years of life. Finally, in column 4 we show that there is no effect of invalidation for patents whose Federal Circuit decision takes place more than 15 years after the filing date. We view these results as a kind of placebo test, providing additional support for the hypothesis that the invalidation effect is not being driven by other unobservable factors.

We also investigated the *time path* of the effect of invalidation on subsequent citations. Figure 3 plots IV estimates of the effect of invalidation in each of the ten years that follow invalidation, and the associated 90-percent confidence intervals. The results show that there is no significant effect in the first two years after Federal Circuit invalidation. Moreover, the effects disappear seven years after the invalidation.<sup>32</sup> This finding suggests that the observed impact of invalidation is not simply due to a ‘media effect’ from press coverage associated with

---

<sup>32</sup>The above estimates are obtained focusing on the 1982-2003 decisions so that for every patent in the sample we have at least seven years of post-decision observations. We ran a variety of robustness checks and found that the qualitative pattern reported in Figure 3 is robust across different samples and specifications. In particular, if we change the sample size by including more recent years or dropping decisions after 2001, we still observe that the statistically significant effects are concentrated in the third to sixth year following invalidation.

the court decision, since one would expect such an effect to generate a more immediate increase in citations, and probably to dissipate over time, which is not what we find. The estimated time path is more compatible with a story of entry of new innovators, previously blocked, developing technology building on the focal patent. In later sections we provide additional evidence which rules out media publicity, and we conduct a detailed analysis of where the blockage occurs, specifically, which technology fields and which types of patentees and downstream innovators.

## 5 Heterogeneous Impacts of Patent Invalidation

### Estimating the Marginal Treatment Effect

To this point we have assumed that the effect of patent invalidation on future citations is constant across patents. However, as the theoretical discussion in Section 2 indicated, the impact of patents on sequential innovation depends on the effectiveness of bargaining, the fragmentation of patent rights, and the risks of coordination failure among downstream developers. Thus we would expect the impact to vary with characteristics of the technology, patentee and market structure. In this section we extend the econometric model to explore this heterogeneity.

We assume that the effect of patent invalidation on future citations can be decomposed into a common component  $\bar{\beta}$  and a random component  $\psi_p$ :  $\beta_p = \bar{\beta} + \psi_p$ . We also assume that the probability of invalidity can be described as

$$Invalidated(JIP_p, X_p) = \begin{cases} 1 & \text{if } P(JIP_p, X_p) \geq v_p \\ 0 & \text{otherwise} \end{cases}$$

where  $v_p$  is a characteristic of the patent case that is unobservable to the econometrician and which affects the invalidity decision. In general, we would expect this unobservable characteristic to be correlated (positively or negatively) with  $\psi_p$ . For example, if the patent is of higher quality (high  $v_p$ ), invalidation would be less likely and the patent would be more likely to be cited after invalidation (high  $\psi_p$ ). This example would imply that  $E(\bar{\beta} + \psi_p | v_p)$  is increasing in  $v_p$ .

Because  $v_p$  is not observed, we cannot condition on it. Nonetheless, for a patent case decided by a panel of judges that is just indifferent between invalidating and not invalidating, it must be that  $P(JIP_p, X_p) = v_p$ . Exploiting this equality, we can identify the marginal treatment effect as  $E(\bar{\beta} + \psi_p | P(JIP_p, X_p))$ , which corresponds to the (heterogenous) effect

of invalidation on future citations for patents that are invalidated because of the instrument. Carneiro, Heckman, and Vytlačil (2010) provide a formal treatment, where they show that

$$E(\bar{\beta} + \psi_p | P = v_p) = \frac{\partial E(\log(PostCites_p + 1) | P)}{\partial P} \Big|_{P=v_p} \quad (7)$$

and establish identification of the marginal treatment effect (MTE).

In Figure 4 we present estimates of the MTE. The horizontal axis depicts the estimated probability that the patent is invalidated. The vertical axis shows the effect of invalidation on post decision citations for different values of this probability. The support for the estimated probability goes from the 10<sup>th</sup> to the 90<sup>th</sup> percentile. The estimated marginal treatment effect is increasing in the probability  $P$ . Patents with low values of  $P$  are those that, given observables, are unlikely to be invalidated. The small and insignificant values for the MTE in this range show that, if an increase in judge propensity to invalidate leads to invalidation of the patent, the effect of invalidation on citations would be negligible. Conversely, patents with high  $P$  are patents with high risk of invalidation based on observable characteristics. For these patents the MTE is positive, indicating that citations increase after invalidation.<sup>33</sup>

The estimated MTE shows substantial heterogeneity in the effect of patent protection on cumulative innovation. The finding of an increasing MTE also helps identify mechanisms that drive the increase in citations that we observe after Federal Circuit invalidation. This is because the MTE estimates the effect of invalidation for patent cases in which judges are indifferent between a validity and an invalidity ruling. Thus, an increasing MTE indicates that the effect of invalidation on citations is greater for patents which, despite having observable features that make invalidation likely (high  $P(JIP_p, X_p)$ ), are characterized by *unobservable factors* that make invalidation less likely (large  $v_p$ ). An example would be characteristics that affect the strength of the patent (legal enforceability) and thus make invalidation less likely, and which are observable to the patentee but *unobservable to the licensees* (and well as the econometrician). This asymmetric information can lead to bargaining failure in licensing negotiations. In such cases, Federal Circuit invalidation can facilitate access to the technology that was blocked by the bargaining failure.

---

<sup>33</sup>These findings are robust to using alternative estimation methods to compute the MTE. Figure 3 plots the MTE computed with a nonparametric approach. We obtain a similar figure using the semiparametric approach (with a third order polynomial) proposed by Carneiro, Heckman, and Vytlačil, (2010).

## Explaining the Heterogeneity

We showed that the effect of patent invalidation on subsequent citations is concentrated among a small subset of patents. We turn now to unbundling the heterogeneous impact of patent rights by relating it to observable characteristics of the technology field and contracting environment.

Previous empirical studies have suggested that two main features of the innovation environment can strongly affect cumulative innovation by shaping the negotiations between upstream and downstream innovators. The first is the concentration of patent rights in the technology field. Ziedonis (2004) argues that when patent ownership is not concentrated (i.e. fragmented), downstream innovators need to engage in multiple negotiations, which exacerbates the risk of bargaining failure and hold-up. For this reason, we expect patents to have a larger blocking effect in fragmented technology fields. The second feature is the ‘complexity’ of the technology field. In complex fields new products tend to rely on numerous patentable elements, as contrasted with ‘discrete’ technology areas where products build only on few patents. When products typically rely on, or incorporate, many patented inputs, licensees engage in multiple negotiations and the risk of bargaining failure is again larger. Thus we expect the impact of patent rights on cumulative innovation to be more pronounced in complex technology fields.

To test these hypotheses, we construct two variables. The first variable, *Conc4*, is a concentration measure equal to the patenting share of the four largest assignees in the technology subcategory of the litigated patent during the five years preceding the Federal Circuit decision (the mean and standard deviation of *Conc4* are 0.067 and 0.053, respectively). The second variable, *Complex*, is a dummy variable for patents in complex technology fields. Building on the findings in Levin et. al. (1987) and Cohen, Nelson and Walsh (2000), we classify as complex the areas of electrical and electronics (NBER category 4), computers and communication (NBER category 2) and medical instruments and biotechnology (NBER subcategories 32 and 33).

In columns 1 and 2 of Table 6 we show, in two split sample regressions, that the effect of patent invalidation is small and statistically insignificant among patents in concentrated technology areas ( $Conc4 \geq \text{median}$ ), whereas it is large and statistically significant among patents in fragmented technology fields ( $Conc4 < \text{median}$ ). Similarly, columns 3 and 4 show

that the effect of invalidation is more than twice as large in complex technology areas as compared to the non-complex technology fields. Column 5 provides estimates using the full sample and interacting *Conc4* and *Complex* with the *Invalidated* dummy. These confirm the findings from the split sample regressions. Evaluated at their respective sample means of *Conc4*, our point estimate (standard error) for complex technology fields is 1.149 (0.29); for non-complex fields it is not statistically different from zero, at 0.167 (0.23). For complex fields the estimate implies that patent invalidation raises subsequent citations by 216 percent. We also confirm that concentration substantially mitigates the effect of patent invalidation on future citations: a one standard deviation increase in *Conc4* reduces the effect of invalidation by 0.37, which is 32 percent of the estimated impact for complex fields.<sup>34</sup>

We can use the parameter estimates from column 5 to compute the implied effect of patent invalidation on citations for each of the technology fields, based on the observed values of *Conc4* and *Complex* for each field. The results, presented in column 1 of Table 7, are striking. There is essentially no effect of patent rights on cumulative innovation in any of the three non-complex technology areas – pharmaceuticals, chemicals and mechanical. By contrast, the effect is large and statistically significant in each of the complex fields – the coefficients imply that invalidation raises citations by 320 percent in medical instruments/biotechnology, 203 percent in electronics and 178 percent in computers. For comparison, column 2 reports estimates of split-sample IV regressions for each technology field. Though the smaller sample sizes reduce precision, the regressions confirm strong impacts in medical instruments/biotechnology and computers, but no statistically significant effect in electronics. Overall, the similarity between the findings in the two columns indicate that the ownership fragmentation and complexity of technology fields are key determinants of the relationship between patents and cumulative innovation.

These findings are important for the policy debates on patent reform. They show that the blocking effect of patent rights depends on identifiable characteristics of the technology field, and are not general. The recent literature studies specific innovations in biotechnology and

---

<sup>34</sup>Column 5 also controls for the direct effect of *Conc4* and includes additive technology dummies that absorb the direct effect of *Complex*. These results are unchanged if we reclassify biotechnology patents (subcategory 33) as a non-complex field, or if we replace the continuous concentration measure with a dummy variable for fields with *Conc4* above the 50th or 75th percentile.

medical instruments and find blocking effects (Murray and Stern, 2007; Murray et. al. 2008 and Williams, 2013), and our estimates confirm these findings using information on diverse innovations within these fields and an entirely different identification strategy. But our results also show that the effects are very different in other fields, and they suggest that legal and regulatory rules to mitigate blocking effects need to target specific technology areas effectively, in order to minimize any damage to overall innovation incentives. At the same time, our findings imply that changes in the contracting environment in which technology licensing takes place would reshape the relationship between patent rights and cumulative innovation.<sup>35</sup>

## 6 Intensive versus Extensive Margins

In the previous section we showed that the blocking effect of patents on later innovation depends on how concentrated patent rights are – i.e., on the ‘industrial organization’ of innovation. However, the influence can also run in the other direction. Patent rights can shape the industrial structure of innovation by impeding the entry of new innovators or the expansion of existing firms, and this potential blocking effect may be stronger for certain kinds of patentees or downstream innovators. In this section we examine this issue and show that the blocking effect of patents depends critically on the size of the patentee and the downstream innovators.

We measure the size of the citing innovators by constructing the portfolio size for each assignee citing the patents involved in Federal Circuit litigation. The portfolio is defined as the number of patents granted to an assignee in the five years before the Federal Circuit decision. The mean portfolio size of citing firms is 359 patents but the distribution is very skewed – the median firm has only 5 patents, and the 75th percentile has 102 patents. We assign firms to one of three size categories: ‘small’ if its portfolio is below five, ‘medium’ if the portfolio is between 6 and 101 patents, and ‘large’ if it greater than 102 patents. We study how patent invalidation affects citations by subsequent innovators in each size group. In each regression we also allow for the effect of invalidation to be different when the focal patent is held by a

---

<sup>35</sup>We also use our parameter estimates (column 5, Table 6) to examine how variation over time within fields affects the impact of invalidation. To do this, we construct the *Conc4* measure for each technology *subcategory* in the years 1982-2002 and compute a weighted average for each of the six broad technology fields, with weights equal to the fraction of patenting in the area. We find no evidence of significant changes in the impact of patent invalidation during our sample period.

large patentee, defined as one with a patent portfolio of more than 102 patents.

In addition, for each size group, we investigate whether the blocking effect of patent rights works through reducing the number of later innovators building on the focal patent or on the intensity of their downstream innovation. This question is of interest because the effect of patent rights on the industrial structure of innovation differs in the two cases. To examine this issue, we decompose the total number of later citations into intensive and extensive margins. We measure the extensive margin by the number of *distinct patent owners (assignees)* citing the focal (litigated) patent in the five-year following the Federal Circuit decision. We measure the intensive margin by the number of *citations per assignee* to the focal patent in the same time window.

Table 8 presents the IV estimates of the patent invalidation effect on citations by different size groups. Focusing first on the total number of external citations (columns 1-3), the estimates reveal that the blocking effect of invalidation is concentrated *exclusively* on citations that patents of large firms receive from small innovators. The magnitude of the implied blocking effect is very large: invalidation of a large firm patent increases small firm citations by about 520 percent. This is consistent with our earlier estimate of 50 percent for the average blocking effect in the overall sample, because roughly 50 percent of the citing entities are small firms in our data and about 20 percent of the patentees are large firms (i.e.,  $520 \times 0.5 \times 0.2 = 52$  percent). The coefficients for the other size groups are much smaller in magnitude and statistically insignificant.<sup>36</sup>

In columns 4-6, we study how patent invalidation affects the extensive margin. The dependent variable in these regressions is the logarithm of one plus the number of distinct assignees citing the litigated patent in the five years following the Federal Circuit decision. Here too we find that the blocking effect of patents is concentrated exclusively among citations

---

<sup>36</sup>Because of sample size, we cannot allow the effect of invalidation to vary with technology field in these regressions (we do allow for additive field effects, however). If citations from small citers to large patentees are overrepresented in fragmented and complex technology fields, where we found blockage was more likely, our finding that blocking effect of invalidation is limited to the large patentee-small citing firm category could be simply a technology field composition effect. To check this concern, we examined the percent of citations in each technology field accounted for by citations by small to large patentees. The technology fields where invalidation has a statistically significant blocking effect (medical instruments, electronics and computers) are not those with the largest fraction of citations from small to large patentees – the mean fraction of sample citations from small to large patentees is 7.4 percent in these fields, as compared to 9.9 percent in the other fields. We conclude that our empirical finding is not due to a technology field composition effect.

by small firms to large firm patents. The estimated coefficient of 1.347 implies a 285 percent increase in the number of distinct small assignees citing the patent when a patent of a large firm is invalidated by the Federal Circuit. The effects for the other size groups again are small and statistically insignificant. Finally, columns 7-9 examine the blocking effect at the intensive margin, the number of citations per distinct patent owner. The only coefficient (marginally) significant is again the one related to large patentees and small citing assignees. The effect of invalidation is about 62 percent, but statistically significant only at the 10 percent level. Overall, we cannot reject the hypothesis that the extensive margin effect for small citing firms is equal to the total effect and that the intensive margin effect is zero.

We conduct extensive robustness checks on the regressions in Table 8. First, we vary the thresholds for defining ‘small’ firms ( $\leq 1, 10$  and  $15$  patents), and for defining large firms ( $\geq 75, 110$  and  $150$  patents). We report the estimates for some of these regressions in Appendix Table A2. Second, we re-estimate the invalidation effects by splitting the samples between large and non-large patentees. We also break down the category of non-large patentees into two groups, small and medium sized firms. In all of these experiments, the pattern that emerges in Table 8 is extremely robust. In every case the effect of invalidation is concentrated on the subsequent citations by small innovators to focal patents held by large firms, and it is predominantly an extensive margin effect.

These findings show that patent rights block later innovation in very specific ways, not uniformly. The fact that we see no statistically significant blocking effect for most size categories suggests that bargaining failure among upstream and downstream innovators is not widespread. However, the results show that bargaining breakdown occurs when it involves large patentees and small downstream innovators.<sup>37</sup> Moreover, our finding that the effect is primarily at the extensive margin suggests that patent rights (held by large firms) may impede the ‘democratization of innovation’ and that the loss of those property rights appears to be associated with greater ‘entry’ of small new innovators.

---

<sup>37</sup>This finding is consistent with Lanjouw and Schankerman (2004), who show that small firms are less able to resolve disputes ‘cooperatively’ without resorting to the courts. One reason for this disadvantage is that small firms do not have patent portfolios that can be useful as counter-threats to resolve disputes or to strike cross-licensing agreements to preserve freedom to operate in their R&D activities (Galasso, 2012).

## 7 Interpreting the Empirical Findings

On average, patent invalidation causes a substantial increase in subsequent citations to the focal patent. This result suggests that some (potentially feasible) licensing deals are not taking place in the presence of patent protection. There are two main reasons why this might occur. First, it might be privately optimal for a patent owner to restrict access if licensing reduces joint profits (e.g., because it intensifies downstream competition). Second, information asymmetry and uncoordinated, multilateral bargaining can lead to licensing failures even when such agreements would increase joint profits. It is important to distinguish between these explanations because they differ in terms of their implications for welfare and policy (even putting aside the effect on consumer surplus).

Our empirical findings suggest that bargaining failure is a significant part of the explanation. The first support for this claim is found in the estimated heterogeneous marginal treatment effects. We found that the impact of patent invalidation is concentrated on a small subset of patents, and that these have unobservable characteristics that are associated with a lower likelihood of being invalidated (i.e., stronger patents). This suggests the presence of asymmetric information that would be expected to induce bargaining failure in licensing. Second, our results also help to pin down *where* the bargaining failure occurs. The effect is concentrated in fields characterized by two features: complex technology and high fragmentation of patent ownership. We find no evidence of blocking in non-complex fields such as chemicals, mechanical, and pharmaceuticals. This reinforces the market failure interpretation, since earlier studies identify fragmentation and complexity as key determinants of licensing breakdown (Cohen, Nelson and Walsh, 2000; and Ziedonis, 2004).<sup>38</sup>

We interpret our finding that patent invalidation increases later citations by other firms as evidence that the focal patent was blocking innovation by those firms. However, there are three

---

<sup>38</sup>Our conclusion that patent rights only block in specific environments may be overly optimistic. An alternative explanation for why we do not find blockage in other settings is that patentees may simply be unable to enforce their rights effectively. In this case the R&D incentives for upstream innovators would be diluted, making welfare implications of patent rights more ambiguous. We do not think that this interpretation is plausible for two reasons. First, our sample covers high-value patents whose owners have expended substantial resources to reach the Federal Circuit court and this does not fit well with an assumption that the associated patent rights are unenforceable. Second, the concentrated, non-complex technology fields are the contexts in which we would expect patents to be more easily enforced, including pharmaceuticals.

possible reasons for believing that this interpretation of our results may lead us to *overestimate* the degree to which patent rights effectively block follow-on innovation. Rather than blocking, the post-invalidation increase in citations could reflect: media publicity, substitution by users from other patents to the focal patent, or strategic citation by downstream innovators . In the remainder of this section we address each of these arguments.

### **Media Publicity from Court Decision**

In order to be confident that our results can be interpreted as patent rights blocking downstream innovation, we need to rule out the possibility that the increase in citation is just driven by publicity associated with the Federal Circuit decision. Our instrumental variable estimation partially addresses this concern, since press coverage is unlikely to be disproportionately greater for patents that have been (randomly) allocated to judges with high propensity to invalidate. Nonetheless, to provide further evidence, we collected data on news coverage for the cases in our sample. Our main source is the Dow Jones Factiva dataset, which collects press releases in the major international news and business publications (e.g. Bloomberg, CNN, New York Times, Wall Street Journal). We classify an article as relevant press coverage if it contains at least one of the names of the litigating parties as well as all the following words: ‘patent’, ‘litigation’, ‘court’ and ‘appeal’. We construct a measure, *MediaMentions*, defined as the number of articles referring to the case in a one-year window centered around the date of the Federal Circuit decision (i.e., six months before and after the decision date).<sup>39</sup> On average, our patent cases have 1.4 media mentions in the one-year window. The variation in media coverage is very large – about 68 percent of cases have no press coverage and, among those with coverage, the mean number of articles is 4.6 (standard deviation=4.7).

When we add *MediaMentions* to our baseline specification, and estimate using our instrumental variation approach, we find no significant effect of the variable on the estimated coefficient on *Invalidated* (column 1 in Table 9). One possible explanation is that the effect of media coverage may be highly non-linear, where only very intense media coverage affects subsequent citations. To explore this idea, we generated a dummy variable *HighPress* equal to one for cases in the top two percent of the *MediaMention* distribution. We find that the

---

<sup>39</sup>The empirical results are similar if we use measures based on two year or six month windows.

media effect is indeed concentrated on appeal cases that receive strong media coverage but our key coefficient on *Invalidated* is robust. Column 2 in Table 9 shows that being in the top two percent of media coverage is associated with a 62 percent increase in citations.<sup>40</sup> This finding supports the idea that publicity about a technology shapes its diffusion and follow-on innovation. Of course, media coverage is endogenous, so we do not claim that this media effect is causal. An examination of exogenous changes in media coverage on follow-on technology remains an interesting topic for future research.

### **Substitution among Patents**

The second concern is that the post-invalidation increase in citations we estimate may be generated by a substitution by downstream innovators away from other patented technologies toward the invalidated patent which are now cheaper to use. However, there are several reasons why we think that this substitution effect is unlikely to account for the entire increase in citations that we estimated. First, our sample comprises highly valuable patents for which litigants spent substantial resources in district court and appeal litigation. It is implausible that such expensive litigation takes place if parties can easily substitute the patented technology with an alternative one. Second, we find that the effect of invalidation is not immediate. This is suggestive that there is no immediate substitution between invalidated patents and alternative technologies. Third, we find that the effect crucially depends on the characteristics of patentees and citers. We see no statistically significant effect for most size categories and find that the increase in citations is more common when it involves large patentees and small downstream innovators. This finding is hard to explain with simple technology substitution, since it is not obvious why an invalidated patent should be used as a substitute technology by small innovators only if it is held by a large patentee.

Nonetheless, we explore this issue in more detail by examining whether patent invalidation also leads to a decline in the number of citations to patents that are putative substitutes for the Federal Circuit patent. To this end, we construct a sample of ‘related’ patents for each

---

<sup>40</sup>We experimented with a variety of percentile cutoffs to define *HighPress*. The publicity effect is present only at very high level of coverage (above 3 percent). However, we find no evidence that the effect of invalidation is different for patents that receive greater press coverage. This provides additional evidence against the concern that media mention may confound the effect of exogenous removal of patent rights estimated in our baseline specification.

litigated patent in our sample. To do this, we use the Google Prior Art software, which is a text based matching algorithm that identifies and ranks related patents. We define a U.S. patent as related to the litigated patent if it has been granted before the decision date and it appears in the top ten related patent documents listed by Google. We collect a maximum of five related patents per focal patent. The Google algorithm identified at least one related patent for 699 Federal Circuit decisions (about 52 percent of our sample).<sup>41</sup>

We run a series of IV regressions to control for the endogeneity of invalidation with the same approach as our baseline regression. The results are reported in Table 9. In column 3, the sample comprises the highest ranked Google match for each Federal Circuit patent (when at least one was identified). Columns 4 and 5 focus, respectively, on the top two and three highest-ranked matches for the Federal Circuit patents. In each of these IV regressions, the estimated coefficient on the patent invalidation dummy is negative, suggesting that there is some role for the substitution interpretation. However, the point estimates are statistically insignificant in two of the samples, and only marginally significant, at the 10 percent level, in the sample using two related patents. Even in the latter case, the estimated coefficient is too small to account for the impact of invalidation on citations to the focal patent. Exponentiation of the point estimate implies that invalidation of the focal patent leads to a 15.5 percent reduction in citations to related patents, which can explain only one fifth of the estimated effect of Federal Circuit invalidation.<sup>42</sup>

We re-estimated the substitution effect exploiting a variety of alternative samples (e.g. balanced samples with top four or five related patents as well as unbalanced samples where we keep all of the related patents identified by Google). All the regressions show a negative relationship between the citations of related patents and invalidation of the focal patent, providing some support for the substitution hypothesis. Nonetheless, the estimates tend to be small and

---

<sup>41</sup>About 27 percent of these observations have only one matched related patent, 20 percent have two related patents and 53 percent have 3 or more related patents. For the Federal Circuit patents for which we were able to find at least one match, we confirm that the estimated causal effect of invalidation on citations is similar to the one obtained in the full sample. Specifically, the IV coefficient is 0.541 (std. error=0.257), implying an increase in citations of approximately 70 percent.

<sup>42</sup>Related patents receive only 48 percent as many citations as Federal Circuit patents (1.2 and 2.5 citations per year, respectively). So a 15.5 percent decline in citations to each of two related patents translates to a 15 percent (2 patents x 0.155 x 0.48) increase in citations to Federal Circuit patents, which is about 1/5 of the 70 percent increase estimated in the sample of matched litigated patents.

statistically insignificant, confirming that the substitution hypothesis cannot explain much of the increase in citation caused by Federal Circuit invalidation.

### **Strategic Citation**

The last alternative interpretation is that the increase in citations caused by patent invalidation may reflect the propensity of small patentees to ‘strategically withhold citations’ to patents of large firms in order to stay below their radar screen, rather than a real blocking impact on the underlying innovation by small firms.<sup>43</sup> There are several reasons why we think that this strategic behavior is unlikely to play a big role in our setting. First, previous studies show that *large firms* are more likely to withhold citations strategically (Lampe, 2011), whereas we find that the effect of invalidation is driven by a rise in citations by *small firms*. Second, our measure includes citations both by the patent applicant and the USPTO examiner. Thus an increase in citations after invalidation would imply not only strategic behavior by the applicants, but also errors by examiners in overlooking relevant prior art. Our estimated impact – a 520 percent increase in citations from small firms – would imply an unreasonably large error rate by patent examiners, especially given that our sample contains well-known ‘superstar’ patents. Finally, the strategic citation interpretation is hard to reconcile with a lagged effect of patent invalidation on later citations, which we documented in Section 4.

## **8 Impact of Invalidation on Self-Citations**

The analysis in the paper has focused on how the loss of the patent right affects external citations, reflecting innovation by other firms. In this last section we explore how patent invalidation affects *self*-citations. In the economics literature, self-citations have been used to measure the extent to which a firm builds on its own past innovation, i.e., to identify its research trajectory, or ‘core competency’ (Jaffe and Trajtenberg, 2002). Examining how invalidation affects self-citations thus reveals how patent rights affect the direction of the firm’s future research activity.

Column 1 of Table 10 shows that Federal Circuit invalidation has no statistically signifi-

---

<sup>43</sup>Small firms may even choose their research niches strategically to avoid coming into conflict with larger players. Lerner (1995) presents some evidence from the biotechnology sector that is consistent with this hypothesis.

cant effect on subsequent self-citations to the focal patent. However, this regression conceals an important distinction between core and non-core patents. The management literature emphasizes the importance of developing a set of core technologies, and effectively protecting them, in order to create a sustainable competitive advantage in the market. This creates the base from which the firm can generate related, complementary (peripheral) innovations. If patent protection over a core technology is lost, we would expect a firm to reorient its research direction away from the development of peripheral innovations building on that technology. This implies that invalidation of a core patent would reduce subsequent self-citations to that patent. However, if a peripheral patent is invalidated, the firm has no incentive to shift research trajectory. To the contrary, loss of a peripheral patent may the firm to intensify efforts to build around the core technology.

To investigate this hypothesis, we construct two alternative measures of core patents, both based on the importance of self-citations. Our first measure, *CORE1*, defines core patents as those for which the number of self-citations received is in the top decile of the firm’s portfolio of patents (constructed as all the patents granted to the patentee in a six-year window centered around the grant date of the litigated patent). One limitation of this measure is that it does not consider the propensity of other firms to cite the focal patent. The second measure, *CORE2*, addresses this by defining core patents as those for which the ratio of self-citations to total citations received is in the top decile of the patents in the overall sample.

Columns 2 and 3 in Table 10 present the IV parameter estimates of the effect of invalidation where we allow the impact to differ for core and non-core patents. Using the measure *CORE1*, we find that invalidation of a core patent generates a 80 percent *reduction* in future self-citations, whereas invalidation of a non-core patent is associated with a 25 percent *increase* in later self-citation. The results in column 3 are similar when we use the alternative *CORE2* measure.<sup>44</sup> These results provide support for the idea that patent rights on core technologies are important for sustaining the research trajectory of firms, and their associated competitive advantages. In this way, patent rights shape the market position of firms and their competitive interaction with other firms. One way to explore these competitive dynamics more fully would

---

<sup>44</sup>We experimented with alternative thresholds to define core patents (from the 90th to 75th percentile) and results are similar to those in Table 10.

be to study how Federal Circuit invalidation of core and non-core patents affects other firms that compete in similar innovation (technology) and/or product markets, building on the recent work of Bloom, Schankerman and Van Reenen (2013).

## 9 Concluding Remarks

In this paper we estimate the causal effect of patent rights on cumulative innovation, using patent invalidation decisions of the Federal Circuit. The identification strategy exploits variation in the propensity of judges to invalidate and the fact that the three-judge panels are generated by a random computer algorithm. There are three key empirical findings. First, invalidation leads to a 50 percent increase in subsequent citations to the focal patent, on average. Second, the impact of patent invalidation is highly heterogeneous, with large variation across patents and technology fields. Third, we find that this effect only occurs between patents owned by large firms that appear to block small innovators. Thus, invalidation of large firm patents ‘democratizes’ innovation by small firms.

Overall, our findings show that patent rights block cumulative innovation only in very specific environments, and this suggests that government policies to address this problem should be targeted. However, scaling back patent rights may not be the most appropriate policy. Theoretical models of cumulative innovation show that such policies have ambiguous effects on overall innovation incentives.<sup>45</sup> It may be preferable to design policies and institutions that facilitate more efficient licensing and thereby promote cumulative innovation, such as the biomedical institutions studied by Furman and Stern (2011).

---

<sup>45</sup>In models with two generations, weaker patent protection shifts rents toward downstream firms, increasing their incentives but reducing incentives for first generation research. The role of patent rights is even more ambiguous in a fully dynamic setting, where each innovation is both upstream and downstream at different stages of its life (Green and Scotchmer, 1995; Hopenhayn, Llobet and Mitchell, 2006).

## Appendix: Microfounding the JIP Measure

We develop a simple model of strategic voting, closely following Feddersen and Pesendorfer (1996). There are three judges  $i \in \{1, 2, 3\}$  who must decide whether a patent is valid ( $V$ ) or not invalid ( $N$ ). Judges are uncertain about the validity of the patent and each judge gets a signal  $v$  or  $n$  that is correlated with the true state. Specifically we assume that

$$\Pr(v|V) = \Pr(n|N) = p_i.$$

The parameter  $p_i \in [\underline{p}, \bar{p}]$  with  $.5 < \underline{p} < \bar{p} < 1$  is the probability that a judge receives the correct signal. The parameter  $p_i$  can be interpreted as the ‘complexity’ of the case for judge  $i$ . The assumption that the signals are private information is standard in the literature on voting. Feddersen and Pesendorfer (1996) provide a number of reasons why the complete disclosure of private information may not occur. For example, some judges may have technical knowledge that is relevant for the case but difficult to communicate. Moreover, differences in preferences for patent validity may reduce the incentives to reveal private information in deliberations.

The judges vote simultaneously either to validate or invalidate and the decision is taken by majority voting. There are two outcomes: either the patent is invalidated (1) or not (0). We assume that each judge maximizes her expected utility and that preferences are given by  $u(1, N) = u(0, V) = 0$  and  $u(1, V) = -q_i$  and  $u(0, N) = -(1 - q_i)$ . The parameter  $q_i$  characterizes the judge’s threshold of reasonable doubt. Let  $\beta_i(n)$  denote the posterior probability for judge  $i$  that the patent is invalid, conditional on obtaining an invalidity signal and being pivotal, i.e that the other two judges,  $x$  and  $z$ , receive different signals from each other. Let  $\beta_i(v)$  denote the posterior probability for judge  $i$  that the patent is invalid, conditional on obtaining a validity signal and being pivotal:

$$\begin{aligned} \beta_i(n) &= \frac{p_i(1 - p_x)p_z}{p_i(1 - p_x)p_z + (1 - p_i)(1 - p_x)p_z} = p_i \\ \beta_i(v) &= \frac{(1 - p_i)(1 - p_x)p_z}{p_i(1 - p_x)p_z + (1 - p_i)(1 - p_x)p_z} = 1 - p_i \end{aligned}$$

Now assume that  $\beta_i(v) < q_i < \beta_i(n)$  for each  $i$ . Feddersen and Pesendorfer (1996) show that if this assumption is satisfied each judge in equilibrium will vote according to his signal (i.e., what they call ‘informative’ voting). More specifically, a pivotal judge receiving an invalidity

signal will vote for invalidity as long as her expected utility is higher from doing so:

$$\beta_i(n)0 - (1 - \beta_i(n))q_i \geq (1 - \beta_i(n))0 - \beta_i(n)(1 - q_i)$$

which is satisfied because we assumed  $q_i < \beta_i(n)$ . She will also vote for validity if she receives a validity signal because  $\beta_i(v) < q_i$ . Moreover, note that  $\beta_i(v) = 1 - p_i$  and  $\beta_i(n) = p_i$ , so the condition for an informative equilibrium is always satisfied as long as  $1 - \underline{p} < q_i < \underline{p}$ .

Let us assume that, for each case, the complexity of the case,  $p_i$ , is an i.i.d. draw from a distribution  $F(p)$  with support  $[\underline{p}, \bar{p}]$  and that  $1 - \underline{p} < q_i < \underline{p}$ . The ex-ante probability that judge  $i$  will vote for invalidity will be  $1 - F(q_i) \equiv f^i$  and the expected number of invalidity votes in the three judge panel will be equal to

$$JIP = f^1 f^2 f^3 + f^1 f^2 (1 - f^3) + f^1 (1 - f^2) f^3 + (1 - f^1) f^2 f^3.$$

Given the random allocation of judges to cases, the sample average of a judge's validity votes will be an unbiased estimator of her probability of voting for validity. Moreover,  $JIP$  is a consistent estimator of the number of validity votes in the three judge panel (it is not unbiased as it is a nonlinear transformation of the  $f^i$ 's).

**Table 1. Summary Statistics**

	Mean	Std. Dev.	Min	Max
Invalidated	0.39	0.49	0	1
Fraction of invalidated claims (conditional on invalidity)	0.72	0.37	0.01	1
PostCites	8.70	19.61	0	409
PostSelfCites	0.63	4.02	0	83
PreCites	21.88	45.99	0	789
PreSelfCites	1.90	6.02	0	109
Claims	17.48	20.47	1	244
Patent Age	9.91	5.15	1	30

NOTES: Sample of 1357 Federal Circuit patent invalidity decisions for period 1983-2008. Invalidated=1 if Federal Circuit invalidates at least one claim of focal patent. PostCites = cites from patents of other assignees in 5 year window after Federal Circuit decision. PostSelfCites = cites from patents owned by same patentee of focal patent in 5 year window after Federal Circuit decision. PreCites = cites from patents of other assignees received before Federal Circuit decision. PreSelfCites = cites received from patents owned by same patentee of focal patent before Federal Circuit decision. Claims = total number of claims listed in focal patent. Patent age = age in years from filing date of patent at Federal Circuit decision.

**Table 2. Comparison of Federal Circuit and other Patents**

	<i>All Granted Patents not litigated</i>	<i>Litigated at Lower Courts and Not Appealed</i>	<i>Litigated at Lower Courts and Appealed</i>
Number of patents	1,808,770	7,216	877
<i>Technology Field Composition (%)</i>			
Drugs and Medical	9.2	12.1	25.7
Chemicals	19.2	11.9	12.7
Computers and Communication	12.5	11.9	12.4
Electronics	17.5	11.6	9.8
Mechanicals	21.3	20.1	15.6
Others	20.4	32.5	23.8
<i>Patent Characteristics</i>			
Cites received per claim	1.0	1.9	2.3
Number of claims	12.5	17.1	19.0
Generality	0.45	0.49	0.49
Originality	0.36	0.39	0.40

NOTES: Sample includes patents granted in period 1980-1999. Cites= total citations received up to 2002. Generality and Originality are defined in Hall et al. (2001). Lower court litigation data are from Lanjouw and Schankerman (2001).

NOTES: \* significant at 10 percent, \*\* significant at 5 percent and \*\*\* significant at 1 percent. Robust standard errors are reported in parentheses. All regressions control for log(PreCites), log(PreSelfCites), log(Claims), age and year effects. PostCites = cites from patents of other assignees in 5 year window after Federal Circuit decision. Invalidated=1 if Federal Circuit invalidates at least one claim of focal patent. Columns 1, 2, and 5 controls for technology class effects. Column 5 also controls for the direct effect of Conc4. Complex=1 if patent is in Computer and Communication (NBER Category 2), Electrical and Electronics (NBER Category 4), Medical Instruments (NBER subcategory 32), and Biotechnology (NBER subcategory 33). Conc4 is the patenting share of the four largest assignees in the technology subcategory of the litigated patent during the five years preceding the Federal Circuit decision. Invalidated and its interactions are instrumented by the Probit estimates of the probability of invalidation and its interactions.

**Table 7. Technology Differences in Invalidation Effect**

<b>Technology</b>	<b>Based on Complex and Conc4 IV Estimates</b>	<b>Split Sample IV Regressions</b>
Chemical	-0.028 (0.242)	-0.710 (0.725)
Mechanical	0.173 (0.230)	-0.225 (0.519)
Drugs	0.229 (0.230)	0.231 (0.449)
Computers and Communications	1.024*** (0.285)	2.388** (1.224)
Electrical and Electronics	1.107*** (0.285)	-2.744 (2.339)
Medical Instruments and Biotechnology	1.435*** (0.313)	2.402*** (0.848)

NOTES: \* significant at 10 percent, \*\* significant at 5 percent and \*\*\* significant at 1 percent. Robust standard errors are reported in parentheses. Estimates in column 1 obtained from column 5 of Table 6 and sample means of Conc4 across various technology areas. Each regression in column 2 controls for log(PreCites), log(PreSelfCites), log(Claims), age and year effects. PostCites = cites from patents of other assignees in 5 year window after Federal Circuit decision. Invalidated=1 if Federal Circuit invalidates at least one claim of focal patent. Invalidated instrumented by the Probit estimates of the probability of invalidation.

**Table 8. Intensive and Extensive Margins (IV Estimates)**

	Total Effect (PostCites Received)			Extensive Margin (Number of distinct Assignees)			Intensive Margin (PostCites per Assignee)		
	1	2	3	4	5	6	7	8	9
	Citing Patents in Small Portfolios	Citing Patents in Medium Portfolios	Citing Patents in Large Portfolios	Citing Patents in Small Portfolios	Citing Patents in Medium Portfolios	Citing Patents in Large Portfolios	Citing Patents in Small Portfolios	Citing Patents in Medium Portfolios	Citing Patents in Large Portfolios
Invalidated	0.075 (0.183)	0.190 (0.168)	0.228 (0.158)	0.036 (0.155)	0.003 (0.105)	0.123 (0.104)	0.025 (0.053)	0.171 (0.105)	0.088 (0.079)

**Table A2. Intensive and Extensive Margins - Robustness (IV Estimates)**

	Total Effect (PostCites Received)			Extensive Margin (Number of Distinct Assignees)		
	1	2	3	4	5	6
	Citing Patents in Small Portfolios ( < 5 patents)	Citing Patents in Small Portfolios ( < 2 patents)	Citing Patents in Small Portfolios ( < 2 patents)	Citing Patents in Small Portfolios ( < 5 patents)	Citing Patents in Small Portfolios ( < 2 patents)	Citing Patents in Small Portfolios ( < 2 patents)
Invalidated	0.046 (0.179)	0.125 (0.168)	0.128 (0.165)	0.015 (0.152)	0.076 (0.143)	0.088 (0.141)
Invalidated X Large Patentee (> 75 patents)	2.552** (1.360)		2.248* (1.277)	1.842** (0.951)		1.390* (0.745)
Invalidated X Large Patentee (> 102 patents)		1.769** (0.752)			1.216** (0.550)	

NOTES: \* significant at 10 percent, \*\* significant at 5 percent and \*\*\* significant at 1 percent. Robust standard errors are reported in parentheses. All regressions control for log(PreCites) in the size group, log(PreSelfCites), log(Claims), age and year effects. PostCites = cites from patents of other assignees in 5 year window after Federal Circuit decision. Invalidated=1 if Federal Circuit invalidates at least one claim of focal patent. Invalidated and its interactions are instrumented by the Probit estimates of the probability of invalidation and its interactions.

Figure A1. Simulated and Estimated Judge Fixed Effects
